CS314 2011 30 Web Protocols

- URI, URN, URL
- Internationalisation
- Role of HTML and XML
- HTTP and HTTPS
 - interacting via the Web

UR what?

- URI: Uniform Resource Identifier
 - Uniquely identifies a data entity
 - Obeys a specific syntax
 - schemeName:specificStuff
- URN: Uniform Resource Name
 - A URI that only names something
 - Example: urn:isbn:0-534-38317-3
- URL: Uniform Resource Locator
 - A URI that points to an actual resource
 - Example: http://en.wikipedia.org/wiki/URL

URI syntax

- URI = scheme ":" hier-part
 ["?" query] ["#" fragment]
- The hierarchical part can start with // and uses / to separate components. There are other reserved characters

http://en.wikipedia.org/wiki/URL

scheme	top of hierarchy (note reversal -	next	next
name	DNS writes right to left!)	level	level

(DNS is case-independent but URI is case-sensitive)

Internationalisation

- The Unicode standard defines character sets for any script
 - variable length character codes, usually encoded in bytes in UTF-8 format
 - 8-bit ASCII is a proper subset of UTF-8
- Internationalising DNS names, URIs and email addresses in UTF-8 is not simple
 - Yet most people in the world have names like Fältström, or write like this 中文 or this ह न्दि
- Web software should support fully internationalised content and interaction

*ML

- In 1969, three IBMers invented GML (Generalised Markup Language)
- In the early 1980s it became SGML (Standard GML)
- Around 1990, Tim Berners-Lee and Robert Cailliau invented HTML (HyperText Markup Language) as an application of SGML
 - HTML is the format for hypertext documents on the Web
- The WorldWide Web Consortium developed XML (eXtensible Markup Language) as a subset of SGML
 primary format for data sharing in Web-based services
- XHTML (eXtensible HTML) is an XML-conformant redefinition of HTML

*ML parsers

- Strictly speaking, a pure SGML parser can parse HTML, XML or XHTML
- In practice, HTML is written sloppily with proprietary extensions
 - browsers and XML consumers have to be more tolerant than a strict SGML parser
 - different browsers tolerate different deviations from the standards
 - HTML files that don't cite a specific DTD (Document Type Definition) or omit some syntax elements are often tolerated by browsers

SGML DTDs

- SGML text starts with a DTD declaration such as
 !DOCTYPE elem1 PUBLIC "fpi" "path">
 elem1= the first SGML element in the document
 fpi = formal public identifier of the DTD
 path = where to find the DTD text
- Example

```
<!DOCTYPE html PUBLIC
"-//W3C//DTD HTML 4.01//EN"
"http://www.w3.org/TR/html4/strict.dtd">
```

*ML document format

- A document must obey its declared DTD
- Thus, with the previous DTD the document must start with <html> and end with </html>
 - Internally, all elements must conform to the syntax defined in the DTD
 - The semantics expressed in comments in the DTD need to be coded into whatever software is interpreting the document

<!DOCTYPE html PUBLIC "-//W3C//DTD HTML 4.01//EN" "http://www.w3.org/TR/html4/strict.dtd"> <html>

<head>

<title>*ML document format</title>

</head>

<body>

<h1>*ML document format</h1>

A document must obey its declared DTD

Thus, with the previous DTD the document must start with &It;html> and end with &It;/html>

Internally, all elements must conform to the syntax defined in the DTD

The semantics expressed in comments in the DTD need to be
coded into whatever software is interpreting the document

</body>

</html>

Getting Hyper

- The key property of an HTML document is that it may contain links to other HTML documents
 - These are called hyperlinks because they may jump anywhere on the Internet, and the resulting interlinked documents are known as hypertext
- A link is formally an anchor in HTML terminology:

Click for Google

a for Anchor

href for Hypertext Reference

HTTP: Hypertext Transfer Protocol

- Used for communication between Web clients ("browsers") and Web servers
 - Principal use is to carry HTML documents identified by a URL
 - Request/response protocol running over TCP (usually port 80)
- Request includes:
 - Method (see below)
 - URI (typically a URL)
 - Request modifiers and optional content
- Response includes:
 - Status or error code
 - Meta-information about content
 - Content (typically an HTML document)

Important HTTP Methods

- GET
 - retrieve the entity indicated by the URI, e.g. an HTML document
- POST
 - post (send) the content in the request message to the server for processing, e.g. filled in forms from an HTML page
- There are various other methods defined, but GET and POST are by far the most important
 - some methods allow for remote content update

Content Encoding in HTTP

- HTTP message format generally resembles email format, and similar methods are used to encode content (international character sets, graphics, etc.)
- Thus, an image represented in an HTML document like this:

```
<img src="CoffeeBreak.jpg">
```

leads to HTTP content headers like this:

```
Content-Length: 49398
```

Connection: close

```
Content-Type: image/jpeg
```

followed by encoded JPEG format

Nested content causes repeated HTTP transactions

<html><body>

- Here's some text and an image in the same directory .
- Here's a
 - link.
- </body></html>
- There will be
 - a GET for the initial document,
 - a second automatic GET on the same HTTP connection for the image,
 - a third GET on a new HTTP connection when the user clicks on the link

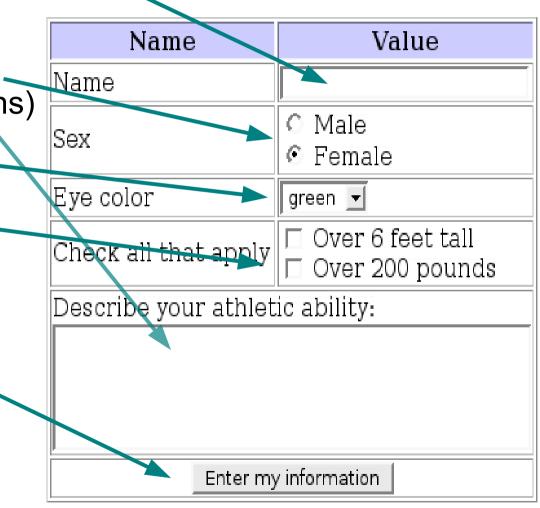

POST and the Interaction Model

• HTML documents can include *forms*, and browsers support data entry into forms

 Browser generates a POST message when user clicks the Send button, and the data entered is delivered to the script

HTML Form Options

- Possible input fields
 - text (one line of free format text)
 - textbox (more text)
 - radio (somebody thought these look like radio buttons)
 - select (a drop-down list)
 - checkbox (tick mark)
 - submit

Scripting (Server Side)

- Data entered in a form is delivered to a script at the server
 - The script must know the fields in the form and their meanings
 - The web server reaches the script through the CGI (Common Gateway Interface)
 - Many choices of scripting language, and ways to use general languages like C and Java
 - Most common today (for complex applications) are Perl, PHP and Ruby on Rails
 - PHP5 is an object-oriented language

Scripting (Client Side)

- HTML content can also include scripts that run on the client machine
 - which, by the way, could include malicious code
 - mainly written in JavaScript
- JavaScript is not Java, but can be embedded in HTML documents
 - weakly typed and rather vaguely defined
 - art rather than science
- HTML content can also trigger Java code

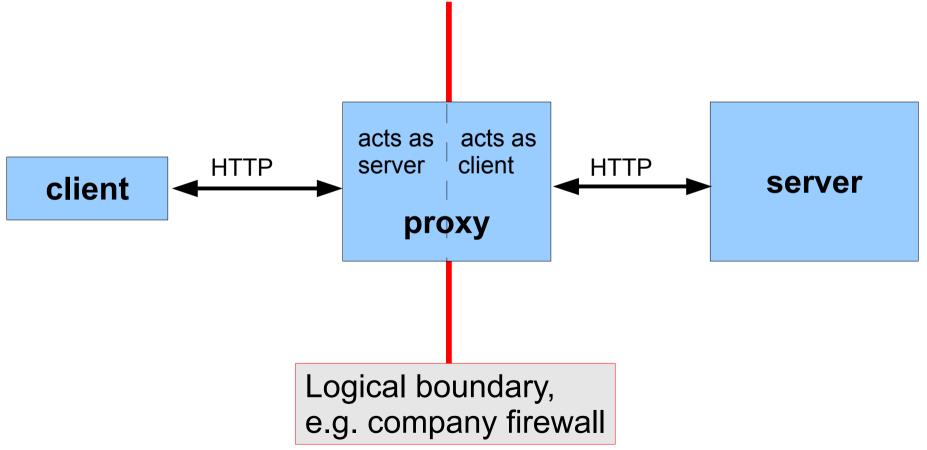

HTTP Caches

- HTTP supports caching
 - locally, in the client system
 - remotely, in an intermediate system
- Caching is obviously beneficial for large images etc.
 - dynamic content must not be cached
 - POST invalidates cached data
- HTTP cache-control directives include:

no-cache #dynamic content
max-age = <seconds>#short-lived data

HTTP Proxies

- An intermediate system can proxy HTTP requests and responses
 - a proxy can be configured as caching or non-caching

HTTP security

- An HTTP connection can be opened securely over TLS (SSL) by using the *https:* scheme
 HTTPS generally listens on port 443
- An insecure HTTP connection can use the HTTP *upgrade* header to upgrade to TLS, even when using port 80
 - the HTTP CONNECT method can be used to upgrade to TLS through a proxy
- Beware! Client authentication can be secured via TLS, but HTTP server authentication is a minefield

Congratulations! You have connected securely to StealMyPassword.net.
