## ABSTRACT

It is shown that the parity game can be solved in quasipolynomial time. The parameterised parity game – with $n$ nodes and $m$ distinct values (aka colours or priorities) – is proven to be in the class of fixed parameter tractable (**FPT**) problems when parameterised over $m$. Both results improve known bounds, from runtime $n^{O(\sqrt{n})}$ to $O(n^{\log(m)+6})$ and from an **XP**-algorithm with runtime $O(n^{\Theta(m)})$ for fixed parameter $m$ to an **FPT**-algorithm with runtime $O(n^5) + g(m)$, for some function $g$ depending on $m$ only. As an application it is proven that coloured Muller games with $n$ nodes and $m$ colours can be decided in time $O((m^m \cdot n)^5)$; it is also shown that this bound cannot be improved to $O((2^m \cdot n)^c)$, for any $c$, unless **FPT = W[1]**.

## KEYWORDS

Parity Games, Muller Games, Quasipolynomial Time Algorithm

## 1 INTRODUCTION

A parity game is given by a directed graph $(V, E)$, a starting node $s \in V$, a function *val* which attaches to each $v \in V$ an integer value (also called colour) from a set $\{1, 2, \ldots, m\}$; the main parameter of the game is $n$, the number of nodes, and the second parameter is $m$. Two players Anke and Boris move alternately in the graph with Anke moving first. A move from a node $v$ to another node $w$ is valid if $(v, w)$ is an edge in the graph; furthermore, it is required that from every node one can make at least one valid move. Anke and Boris own certain values. The alternate moves by Anke and Boris and Anke and Boris and . . . define an infinite sequence of nodes which is called a play. The values of the nodes can always be chosen such that one player wins at the even numbers and the other player wins at the odd numbers. Anke wins a play through nodes $a_0, a_1, \ldots$ iff the limit superior (that is, the largest value appearing infinitely often) of the sequence $val(a_0), val(a_1), \ldots$ is a number she owns, that is, a number of her parity. The following figure provides an example of a parity game.

In this example, the nodes are labeled with their values, which are unique (but this is not obligatory); furthermore, Anke has even and Boris has odd parity. Boris has now the following memoryless (that is, moves are independent of the history) winning strategy for this game: $1 \to 1$, $2 \to 3$, $3 \to 3$, $4 \to 5$, $5 \to 5$. Whenever the play leaves node 1 and Anke moves to node 2, then Boris will move to node 3. In case Anke moves to node 4, Boris will move to node 5. Hence, whenever the play is in a node with even value (this only happens after Anke moved it there), in the next step the play will go into a node with a higher odd value. So the largest infinitely often visited node value is odd and therefore the limit superior of these numbers is an odd number which justifies Boris' win. Hence Boris has a winning strategy for the parity game given above.

For parity games, in general, the winner can always use a *memoryless winning strategy* [5, 28, 48, 49, 64]. This fact will be one central point in the results obtained in this paper: the parity game will be augmented with a special statistics – using polylogarithmic

space – which indicates the winner correctly after a finite time whenever the winner employs a memoryless winning strategy.

It should be pointed out that one can also consider games where it only depends on the node which player moves and the players do not necessarily take turns. Both versions of parity or Muller games can be translated into each other with a potential increase of the number of nodes by a factor 2. In the case that one goes from turn-based to position-based Muller games, one doubles up each node: Instead of the node $v$ one uses a node (Anke, $v$), when it is Anke's turn to move, and a node (Boris, $v$), when it is Boris' turn to move. For the other direction, each node $w$ receives a prenode $w'$ with exactly one outgoing edge from $w'$ to $w$. Now, for each edge $(v, w)$ from the original game, if the same player moves at $v$ and at $w$ in the original game, then one puts the edge $(v, w')$ into the new game, else one puts the edge $(v, w)$ into the new game. The rationale behind this is that the longer path $v - w' - w$ has even length in the case that the players moving at $v$ and $w$ should be the same for alternating moves. Furthermore, if Anke moves at the original starting node $s$, then $s$ is also the starting node of the new game, else $s'$ is the starting node of the new game.

Parity games are a natural class of games which are not only interesting in their own right, but which are also connected to fundamental notions like $\mu$-calculus, modal logics, tree automata and Muller games [3, 6, 7, 14, 27, 28, 38, 57, 61–63]. A possible application of good algorithms to solve parity games would be that one gets better algorithms to decide the theory of certain tree automatic structures [23, 24, 47] and to employ such algorithms in order to understand these structures better.

For investigating the complexity side of the game, it is assumed that the game is given by a description in size polynomial in the number $n$ of nodes and that one can evaluate all relevant parts of the description in logarithmic space. A possibility is to store the following three items for each game (where Anke moves first and starts from node 1):

- two numbers $m, n$ with $1 \leq m \leq n$ and one bit which says whether the values owned by player Anke are the even or the odd numbers;
- the game graph given by a table, that is, for each pair of nodes, a bit which says whether there is a directed edge between the two nodes or not;
- the values of the nodes given by another table which holds, for each node, a binary number from $\{1, 2, \ldots, m\}$.

An important open problem for parity games is the *time complexity* for finding the winner of a parity game, when both players play optimally; the first algorithms took exponential time [48, 64] and subsequent studies searched for better algorithms [40, 42, 44, 51, 56–58]. Many researchers, including Emerson and Jutla [28] in 1991, asked whether the winner of a parity game can be determined in polynomial time.

Emerson, Jutla and Sistla [29] showed that the problem is in **NP ∩ co-NP** and Jurdzinski [41] improved this bound to **UP ∩ co-UP**. This indicates that the problem is not likely to be hard for **NP** and might be solvable faster than in exponential time. Indeed, Petersson and Vorobyov [51] devised a subexponential randomised algorithm and Jurdzinski, Paterson and Zwick [44] a deterministic algorithm of similar complexity (more precisely, the subexponential

complexity was approximately $n^{O(\sqrt{n})}$). Besides this main result, there are also various practical approaches to solve special cases [3, 19, 32] or to test out and analyse heuristics [10, 35, 42]; however, when Friedmann and Lange [30] compared the various parity solving algorithms from the practical side, they found that Zielonka's recursive algorithm [64] was still the most useful one in practice. McNaughton [48] showed that the winner of a parity game can be determined in time $n^{m+O(1)}$ and this was subsequently improved to $n^{m/2+O(1)}$ [8, 59] and to $n^{m/3+O(1)}$ [56, 58], where $n$ is the number of nodes and $m$ is the maximum value (aka colour aka priority) of the nodes.

The consideration of the parameter $m$ is quite important; it is a natural ingredient of the parity games. Schewe [57, 58] argues that for many applications which are solved using parity games, the parameter $m$ is much smaller than $n$, often by an exponential gap. For example, when translating coloured Muller games into parity games in the way done by McNaughton [48] and Björklund, Sandberg and Vorobyov [4], the number of values is, for all but finitely many games, bounded by the logarithm of the number of nodes, see the proof of Theorem 3.4 below. Similarly, an important application of parity games is the area of reactive synthesis. Here one translates LTL-formulas into a Büchi automaton which needs to be determinised by translating it into a parity automaton. Building on work of Safra [54, 55], Piterman [52] showed that he can translate non-deterministic Büchi automata with $n$ states into parity automata with $2 \cdot n^n \cdot n!$ states and $2n$ values. In other words, he can evaluate various conditions on these parity automata by determining the winner in the corresponding parity game. Also Di Stasio, Murano, Perelli and Vardi [18] investigated in their experiments various scenarios where the number $m$ is logarithmic in $n$. The present work takes therefore the parameter $m$ into consideration and improves the time bounds bounds in two ways:

- The overall time complexity is $O(n^{\lceil \log(m) \rceil + 6})$ which provides a quasipolynomial bound on the runtime, as one can always choose $m \leq n$.
- Furthermore, if $m < \log(n)$, then the overall time complexity is $O(n^5)$, which shows that the problem is fixed parameter tractable when parameterised by $m$; the parity games are therefore in the lowest time complexity class usually considered in parameterised complexity.

Prior investigations have already established that various other parameterisations of parity games are fixed-parameter tractable, but the parameterisation by $m$ was left open until now. Chatterjee [12] pointed out to the authors that one can also write the result in a product form with Parity Games be solvable in time $O(2^m \cdot n^4)$ for all $m, n$; the proof uses just the methods of Theorem 2.8 but keeping $m$ as a parameter and not using explicitly the bound of $m \leq \log(n)$ which, when invoked into above formula, would give the bound $O(n^5)$.

An application of the results is that coloured Muller games with $n$ nodes and $m$ colours can be decided in time $O((m^m \cdot n)^5)$; Theorem 3.5 and Corollary 3.6 below show that this bound cannot be improved to $O((2^m \cdot n)^c)$ for any $c$ unless **FPT = W[1]**.

Subsequent research [22, 33, 43, 60] has provided the additional runtime bound

$$O(\lceil m/\log(n) \rceil^4 \cdot n^{3.45 + \log(\lceil m/\log(n) \rceil + 2)})$$

where the bound cited here stems from Stephan's teaching material [60, Theorem 20.22] while the research papers [22, 33, 43] obtained slightly better bounds due to some assumptions they make on the game and due to the usage of better bounds for binomials. However, the main contribution of the subsequent research [22, 43] is that the quasipolynomial time algorithm can be modified such that in addition to the time bound the workspace the algorithm uses is only quasilinear in the number of nodes $n$. This improves over the here presented algorithm which uses quasipolynomial space. Furthermore, various authors provided their own version of the verification of the algorithm presented in this paper [22, 33, 43]. Before presenting the results, the basic properties of the two games (parity and Muller) is given by the following summary.

1. A *game* is given by a directed finite graph of $n$ nodes, a starting node and a set $G$ of sets of nodes which are called the *winning set* of player Anke.

2. Two players, Anke and Boris, move alternately a marker through the graph, starting from some starting node and each time along an outgoing edge of the current position; without loss of generality, every node has at least one outgoing edge (which can go to the node itself). In certain cases, one also considers games in a framework where the current node and not the turn determines which player moves; both types of games can be translated into each other in polynomial time and the number of nodes doubles at most.

3. A *play* is the infinite sequence of nodes visited by the marker while Anke and Boris are playing. To decide the *winner of a play*, one considers the set of infinitely often visited nodes $U$. Now Anke wins the play iff $U \in G$. Both types of games, parity games and coloured Muller games, equip the nodes with additional information (values or colours) and say that $G$ must respect this information. In these cases, $G$ depends only on the values or colours of the members of $U$ itself.

4. For *parity games*, the additional information is that each nodes carries a value from $\{1, 2, \ldots, m\}$ and then $G$ either contains all sets $U$ where the maximal value of a node in $U$ is odd (in this case, Anke has odd parity and Boris has even parity) or contains all sets $U$ where the maximal value of a node in $U$ is even (in this case, Anke has even parity and Boris has odd parity).

5. For *coloured Muller games*, each node has a colour and the colours of set $U$ of nodes is the set of all colours which are taken by some nodes in $U$. Furthermore, $G$ respects the colours in the sense that for every set $U \in G$ and every set $U'$ of nodes having the same colours as $U$, it holds that also $U' \in G$. So one could represent $G$ also as the set of all combinations of colours where Anke wins. An equivalent model is to permit multiple colours (including none) per node, which is sometimes more succinct and clearer to write; if such a game has $m$ colours and $n$ nodes, it can be translated in polynomial time into an equivalent standard game, that is, into a coloured Muller game with same winner which has exactly one colour per node, where the overall number of colours is $m + 1$ and number of nodes is $n \cdot (m + 1)$.

6. The number $m$ of colours used in the game is an important parameter of coloured Muller games; for complexity-theoretic considerations, the exact complexity class of solving coloured Muller games with $n$ nodes and $m$ colours might also depend on how $G$ is represented, in particular in the case that $m$ is large, the size of that formula (which in turn might depend on the way it is represented) is a further parameter. However, this parameter is not studied in the present work.

7. A *strategy for a player*, say for Anke, maps, for every situation where Anke has to move, the current position and history of previous moves to a suggested move for Anke. A *winning strategy* for Anke is a strategy for Anke which guarantees that Anke wins a play whenever she follows the suggested moves. A strategy is called *memoryless* iff it only depends on the current node and not on any other aspects of the history of the play.

8. The *winner of a game* is that player who has a winning strategy for this game. Parity games and Muller games always have a winner and this winner wins every play in the case that the winner follows a winning strategy.

## 2 THE COMPLEXITY OF THE PARITY GAME

The main result in this section is an alternating polylogarithmic space algorithm to decide the winner in parity games; later more concrete bounds will be shown. The idea is to collect for both players in the game, Anke and Boris, in polylogarithmic space statistics over their performance in the play: these statistics store information about whether the play has gone through a loop where the largest valued node has the parity of the corresponding player.

The following notation will be used throughout the paper. In order to avoid problems with fractional numbers and $\log(0)$, let $\lceil \log(k) \rceil = \min\{h \in \mathbb{N} : 2^h \geq k\}$. Furthermore, a function (or sequence) $f$ is called *increasing* whenever for all $i, j$ the implication $i \leq j \Rightarrow f(i) \leq f(j)$ holds.

**Theorem 2.1.** *There exists an alternating polylogarithmic space algorithm deciding which player has a winning strategy in a given parity game. When the game has $n$ nodes and the values of the nodes are in the set $\{1, 2, \ldots, m\}$, then the algorithm runs in $O(\log(n) \cdot \log(m))$ alternating space.*

**Proof.** The idea of the proof is that, in each play of the parity game, one maintains winning statistics for both players Anke and Boris. These statistics are updated after every move for both players. In case a player plays according to a memoryless winning strategy for the parity game, the winning statistics of this player will eventually indicate the win (in this case one says that the "winning statistics of the player mature") while the opponent's winning statistics will never mature. This will be explained in more detail below.

The winning statistics of Anke (Boris) has the following goal: to track whether the play goes through a loop where the largest value of a node in the loop is of Anke's (Boris') parity. Note that if Anke follows a memoryless winning strategy then the play will eventually go through a loop and the node with the largest value occurring in any loop the play goes through is always a node of Anke's parity. Otherwise, Boris can repeat a loop with the largest value being of Boris' parity infinitely often and thus win, contradicting that Anke is using a memoryless winning strategy.

The naive method to do the tracking is to archive the last $2n + 1$ nodes visited, to find two identical moves out of the same node by the same player and to check whose parity has the largest value

between these two moves. This would determine the winner in the case that the winner uses a memoryless winning strategy. This tracking needs $O(n \cdot \log(n))$ space – too much space for the intended result. To save space one constructs a winning statistics which still leads to an Anke win in case Anke plays a memoryless winning strategy, but memorises only partial information.

The winning statistics of the players are used to track whether certain sequences of nodes have been visited in the play so far and the largest value of a node visited at the end or after the sequence is recorded. The definitions are similar for both players. For simplicity the definition is given here just for player Anke.

**Definition 2.2.** *In Anke's winning statistics, an $i$-sequence is a sequence (not necessarily consecutive, but in order) of nodes $a_1, a_2, , a_3,$ $, \dots, a_{2^i}$ which has been visited during the play so far such that, for each $k \in \{1, 2, 3, \dots, 2^i - 1\}$, the maximum value of the nodes visited between $a_k$ and $a_{k+1}$, that is, $\max\{val(a) : a = a_k \vee a = a_{k+1} \vee a$ was visited between $a_k$ and $a_{k+1}\}$, is of Anke's parity.*

The aim of Anke is to find a sequence of length at least $2n+1$, as such a sequence must contain a loop. So she aims for an $(\lceil \log(n) \rceil + 2)$-sequence to occur in her winning statistics. Such a sequence is built by combining smaller sequences over time in the winning statistics.

Here a winning statistics $(b_0, b_1, \dots, b_{\lceil \log(n) \rceil + 2})$ of a player consists of $\lceil \log(n) \rceil + 3$ numbers between 0 and $m$ where $b_i = 0$ indicates that currently no $i$-sequence is being tracked and $b_i > 0$ indicates that

> **Property-$b_i$:** an $i$-sequence is being tracked and that the largest value of a node visited at the end of or after this $i$-sequence is $b_i$.

Note that for each $i$ at most one $i$-sequence is tracked. The value $b_i$ is the only information of an $i$-sequence which is kept in the winning statistics.

The following invariants are kept throughout the play and are formulated for Anke's winning statistics; those for Boris' winning statistics are defined with the names of Anke and Boris interchanged. In the description below, "$i$-sequence" always refers to the $i$-sequence being tracked in the winning statistics.

(I1) Only $b_i$ with $0 \leq i \leq \lceil \log(n) \rceil + 2$ are considered and each such $b_i$ is either zero or a value of a node which occurs in the play so far.

(I2) An entry $b_i$ refers to an $i$-sequence which occurred in the play so far iff $b_i > 0$.

(I3) If $b_i, b_j$ are both non-zero and $i < j$ then $b_i \leq b_j$.

(I4) If $b_i, b_j$ are both non-zero and $i < j$, then in the play of the game, the $i$-sequence starts only after a node with value $b_j$ was visited at or after the end of the $j$-sequence.

When a play starts, the winning statistics for both players are initialised with $b_i = 0$ for all $i$. During the play when a player moves to a node with value $b$, the winning statistics of Anke is updated as follows – the same algorithm is used for Boris with the names of the players interchanged everywhere.

1. If $b$ is of Anke's parity or $b > b_i > 0$ for some $i$, then one selects the largest $i$ such that
   (a) either $b_i$ is not of Anke's parity – that is, it is either 0 or of Boris's parity – but all $b_j$ with $j < i$ and also $b$ are of Anke's parity

   (b) or $0 < b_i < b$
   and then one updates $b_i = b$ and $b_j = 0$ for all $j < i$.
2. If this update produces a non-zero $b_i$ for any $i$ with $2^i > 2n$ then the play terminates with Anke being declared winner.

Note that it is possible that both 1.(a) and 1.(b) apply to the same largest $i$. In that case, it does not matter which case is chosen, as the updated winning statistics is the same for both cases. However, the tracked $i$-sequences referred to may be different; this does not effect the rest of the proof.

**Example 2.3.** *Here is an example of $i$-sequences for player Anke. This example is only for illustrating how the $i$-sequences and $b_i$'s work; in particular this example does not use memoryless strategy for any of the players. Consider a game where there is an edge from every node to every node (including itself) and the nodes are $\{1, 2, \dots, 7\}$ and have the same values as names; Anke has odd parity. Consider the following initial part of a play:*

1 6 7 5 1 4 5 3 2 1 3 2 2 3 1 3 3 1

*The $i$-sequences and the $b_i$'s change over the course of above play as given in the following table. In the table, the nodes prefixed by "$i$ :" are the nodes of the corresponding $i$-sequence.*

| Move | $b_4, \dots, b_0$ | $i$-sequences in play so far | rule |
|------|------|------|------|
| 1 | 0,0,0,0,1 | 0:1 | 1.(a) |
| 6 | 0,0,0,0,6 | 0:1 6 | 1.(b) |
| 7 | 0,0,0,0,7 | 1 6 0:7 | 1.(a) |
| 5 | 0,0,0,5,0 | 1 6 1:7 1:5 | 1.(a) |
| 1 | 0,0,0,5,1 | 1 6 1:7 1:5 0:1 | 1.(a) |
| 4 | 0,0,0,5,4 | 1 6 1:7 1:5 0:1 4 | 1.(b) |
| 5 | 0,0,0,5,5 | 1 6 1:7 1:5 1 4 0:5 | 1.(a) |
| 3 | 0,0,3,0,0 | 1 6 2:7 2:5 1 4 2:5 2:3 | 1.(a) |
| 2 | 0,0,3,0,0 | 1 6 2:7 2:5 1 4 2:5 2:3 2 | |
| 1 | 0,0,3,0,1 | 1 6 2:7 2:5 1 4 2:5 2:3 2 0:1 | 1.(a) |
| 3 | 0,0,3,3,0 | 1 6 2:7 2:5 1 4 2:5 2:3 2 1:1 1:3 | 1.(a) |
| 2 | 0,0,3,3,0 | 1 6 2:7 2:5 1 4 2:5 2:3 2 1:1 1:3 2 | |
| 3 | 0,0,3,3,3 | 1 6 2:7 2:5 1 4 2:5 2:3 2 1:1 1:3 2 0:3 | 1.(a) |
| 1 | 0,1,0,0,0 | 1 6 3:7 3:5 1 4 3:5 3:3 2 3:1 3:3 2 3:3 3:1 | 1.(a) |
| 3 | 0,3,0,0,0 | 1 6 3:7 3:5 1 4 3:5 3:3 2 3:1 3:3 2 3:3 3:1 3 | 1.(b) |
| 3 | 0,3,0,0,3 | 1 6 3:7 3:5 1 4 3:5 3:3 2 3:1 3:3 2 3:3 3:1 3 0:3 | 1.(a) |
| 1 | 0,3,0,1,0 | 1 6 3:7 3:5 1 4 3:5 3:3 2 3:1 3:3 2 3:3 3:1 3 1:3 1:1 | 1.(a) |

*If at an update of an $i$-sequence both possible updates 1.(a) and 1.(b) apply to the same level $i$ then it does not matter for the statistics which is chosen. However, for the $i$-sequences, one has to commit to one choice and for simplicity, (for the above table) one assumes that 1.(a) has priority. So the formal algorithm for updating the sequences is the following one.*

1. *If $b$ is of Anke's parity or $b > b_i > 0$ for some $i$, then one selects the largest $i$ such that*
   (a) *either $b_i$ is not of Anke's parity – that is, it is either 0 or of Boris's parity – but all $b_j$ with $j < i$ and also $b$ are of Anke's parity*

   (b) *or $0 < b_i < b$.*
   *else there is no update and one goes to step 3.*
2. *For the selected $i$, one does the following update according to the first of the two above cases which applies:*
   (a) *Let $b_i = b$ and let the $i$-sequence contain all the nodes of the $j$-sequences with $j < i$ in that order plus the new node with*

value $b$ and let $b_j = 0$ for all $j < i$ as the corresponding $j$-sequences are merged into the new $i$-sequence;

(b) Let $b_i = b$ and let the $i$-sequence be unchanged except for the update of the associated value $b_i$. Furthermore, all $j$-sequences with $j < i$ are made void by setting $b_j = 0$ for all $j < i$.

Furthermore, all $j$-sequences with $j > i$ are maintained as they are.

3. If this update produces a non-zero $b_i$ for any $i$ with $2^i > 2n$ then the play terminates with Anke being declared winner and no further tracking of $i$-sequences is needed.

The 3-sequence in the above table has already a loop, as there are three occurrences of "3 : 3" and the second and third of these have that the same player moves. However, as the sequences are not stored but only the $b_i$, Anke's winning statistics only surely indicates a win of player Anke when there is an $i > \log(2n + 1)$ with $b_i > 0$; this $i$ is 4 as $2^4 > 2 \cdot 7 + 1$.

**Verification of the algorithm.** Note that, in the updating algorithm for Anke's winning statistics, if $b$ is of Anke's parity, then there is an $i$ that satisfies 1.(a), as otherwise the algorithm would have terminated earlier. Initially, the invariants clearly hold as all $b_i$'s are 0. Now it is shown that the invariants are preserved at updates of the $b_i$'s according to cases 1.(a) or 1.(b).

It is easy to verify that the invariants are maintained if the update is done due to 1.(b), and it also ensures that Property-$b_i$ is maintained for the $i$-sequences being tracked. In case the update is done due to 1.(a), then the Property-$b_{i'}$ is maintained for all $i'$-sequences being tracked for $i' > i$ (with $b_{i'} \geq b$ in these cases). For $i' < i$, $b_{i'}$ is made 0 by the update algorithm. The next paragraph argues about an appropriate $i$-sequence being formed. Thus, it is easy to verify that (I1) to (I4) are maintained by the update algorithm. Note that (I1) implies that the space bound needed is at most $O(\log n \log m)$, (I2) is used implicitly to indicate which $i$-sequences are being tracked, and (I3) gives the order of the $i$-sequences tracked: a $(j + 1)$-sequence appears earlier in the play than $j$-sequence. This is used implicitly when one combines the smaller $j$-sequences into a larger one as mentioned below.

When updating Anke's winning statistics by case 1.(a), one forms a new $i$-sequence of length $2^i$ by putting the older $j$-sequences for $j = i - 1, i - 2, \ldots, 1, 0$ together and appending the newly visited one-node sequence with value $b$; when $i = 0$, one forms a new 0-sequence of length $2^0$ consisting of just the newly visited node with value $b$. Note that in case $i > 0$ both $b$ and $b_0$ are of Anke's parity and therefore the highest valued node between the last member $a$ of the older 0-sequence and the last node in the new $i$-sequence (both inclusive) has the value $\max\{b_0, b\}$ (by (I4) and Property-$b_0$ for the older 0-sequence). Furthermore, for every $j < i - 1$, for the last node $a$ of the older $(j + 1)$-sequence and the first node $a'$ of the older $j$-sequence, in the new $i$-sequence a highest valued node in the play between these two nodes $a, a'$ (both inclusive) has value $b_{j+1}$ (by (I4) and Property-$b_{j+1}$ of older $(j + 1)$-sequence) which, by choice, has Anke's parity. Thus the overall combined new sequence indeed satisfies the properties needed for an $i$-sequence, $b$ is the value of the last node of this sequence and thus, currently, also the largest value of a node visited at or after the end of the sequence.

All older $j$-sequences with $j < i$ are discarded and thus their entries are set back to $b_j = 0$.

The same rules apply to the updates of Boris' winning statistics with the roles of Anke and Boris interchanged everywhere.

**Claim 2.4.** *If a player is declared a winner by the algorithm, then the play contains a loop with its maximum valued node being a node of the player.*

To prove the claim, it is assumed without loss of generality that Anke is declared the winner by the algorithm. The play is won by an $i$-sequence being observed in Anke's winning statistics with $2^i > 2n$; thus some node occurs at least three times in the $i$-sequence and there are $h, \ell \in \{1, 2, 3, \ldots, 2^i\}$ with $h < \ell$ such that the same player moves at $a_h$ and $a_\ell$ and furthermore $a_h = a_\ell$ with respect to the nodes $a_1, a_2, a_3, \ldots, a_{2^i}$ of the observed $i$-sequence. The maximum value $b'$ of a node between $a_h$ and $a_\ell$ in the play is occurring between some $a_k$ and $a_{k+1}$ (both inclusive) for a $k$ with $h \leq k < \ell$. Now, by the definition of an $i$-sequence, $b'$ has Anke's parity. Thus a loop has been observed for which the maximum value of a node in the loop has Anke's parity.

**Claim 2.5.** *If a player follows a memoryless winning strategy, then the opponent is never declared a winner.*

To prove the claim, suppose that a player follows a memoryless winning strategy but the opponent is declared a winner. Then the opponent, by Claim 2.4, goes into a loop with the maximum node of the opponent's parity. Hence, the opponent can cycle in that loop forever and win the play, a contradiction.

**Claim 2.6.** *If a player follows a memoryless winning strategy then the player is eventually declared a winner.*

To prove the claim, it is assumed that the player is Anke, as the case of Boris is symmetric. The values $b_i$ analysed below refer to Anke's winning statistics. Assume that the sequence of values of the nodes in an infinite play of the game has the limit superior $c$ which, by assumption, is a value of Anke's parity. To prove the claim one needs to argue that eventually $b_{\lceil \log n \rceil + 2}$ becomes non-zero. For this purpose it will be argued that some counter associated with the values of $b_i$'s eventually keeps increasing (except for some initial part of the play, where it may oscillate). This is argued by using $count(c, t)$ below, which gives the value of the counter after $t$ steps of the play.

Consider a step as making a move and updating of the statistics. For each step $t$ let $b_k(t)$ refer to the value of $b_k$ at the end of step $t$ (that is, after the updates in the statistics following the $t$-th move in the play). Let $B_c(t)$ be the set of all $k$ such that $b_k(t)$ has Anke's parity and $b_k(t) \geq c$. Now define

$$count(c, t) = \sum_{k \in B_c(t)} 2^k$$

Now it is shown that whenever at steps $t, t'$ with $t < t'$, a move to node with value $c$ was made and no move, strictly between steps $t, t'$, was made to any node with value $c' \geq c$, then $count(c, t) < count(c, t')$. To see this, let $i$ be the largest index for which there is a step $t''$ with $t < t'' \leq t'$ such that $b_i$ is updated at step $t''$.

Note that this implies $[b_i(t) < c$ or $b_i(t)$ is of Boris's parity$]$, and $[0 < b_i(t'') \leq c]$. Now, in the case that $b_i(t'') < c$, it holds that $t'' < t'$ and at time $t'$, condition 1.(b) of the update algorithm

will ensure that an update (either 1.(a) or 1.(b)) is done to enforce $b_i(t') = c$. Thus

$$count(c, t') - count(c, t) \geq 2^i - \sum_{j \in B_c(t): j < i} 2^j \geq 1.$$

Accordingly, once all moves involving nodes larger than $c$ in value have been done in the play, there will still be infinitely many moves to nodes of value $c$ and for each two subsequent such moves at $t, t'$ the inequality $count(c, t) + 1 \leq count(c, t')$ will hold. Consequently, the number $count(c, t)$, for sufficiently large $t$ where a move to a node with value $c$ is made at step $t$, rely on some $i$ with $b_i(t) \geq c$ and $2^i > 2n$ and later the termination condition of Anke will terminate the play with a win.

The above arguments show that a alternating Turing machine can simulate both players and, taking the winning statistics into account, will accept the computation whenever Anke has a winning strategy for the game. Besides the winning statistics, the alternating Turing Machine only needs to keep track of the current node in the play and the player who is to move next. Thus, the alternating Turing machine uses only $O(\log(n) \cdot \log(m))$ space to decide whether the parity game, from some given starting point, will be won by Anke (or Boris), provided the winner plays a memoryless winning strategy (which always exists when the player can win the parity game). □

Chandra, Kozen and Stockmeyer [11] showed how to simulate an alternating Turing machine working in polylogarithmic space by a deterministic Turing machine working in quasipolynomial time. Their simulation bounds for the alternating Turing machine described in Theorem 2.1 give a deterministic Turing machine working in time $O(n^{c \log(m)})$ for some constant $c$. As mentioned above, one can always assume that in a parity game with $n$ nodes, with values from $\{1, 2, \ldots, m\}$, one can choose $m \leq n$, so one gets the following parameterised version of the main results that parity games can be solved in quasipolynomial time.

**Theorem 2.7.** *There is an algorithm which finds the winner of a parity game in time $O(n^{c \log(m)})$ for a parity game with $n$ nodes and values from $\{1, 2, \ldots, m\}$, with $m \leq n$.*

For some special choices of $m$ with respect to $n$, one can obtain even a polynomial time bound. McNaughton [48] showed that for every constant $m$, one can solve a parity game with $n$ nodes having values from $\{1, 2, \ldots, m\}$ in time polynomial in $n$; however, in all prior works the degree of this polynomial depends on $m$ [31]; subsequent improvements were made to bring the dependence from approximately $n^{m+O(1)}$ first down to $n^{m/2+O(1)}$ [8, 59] and then to approximately $n^{m/3+O(1)}$ [42, 58]. The following theorem shows that one can bound the computation time by a fixed-degree polynomial in $n$, for all pairs $(m, n)$ with $m < \log(n)$.

**Theorem 2.8.** *If $m < \log(n)$ then one can solve the parity game with $n$ nodes having values from $\{1, 2, \ldots, m\}$ in time $O(n^5)$.*

**Proof.** Note that Theorem 2.1 actually shows that the following conditions are equivalent:

- Anke can win the parity game.
- Anke can play the parity game such that her winning statistics matures while Boris' winning statistics does not mature.

Thus one can simplify the second condition and show that it is equivalent to the following two games [46, 60]:

- One only maintains Anke's winning statistics and a play terminates with a win for Anke iff she is eventually declared a winner and the play is a win for Boris iff it runs forever.
- One only maintains Boris' winning statistics and a play is a win for Anke iff it never happens that the winning statistics of Boris make him to be declared a winner.

The first game is called a reachability game [46] and the second game a survival game [60, Chapter 9]. Both games are isomorphic, as they are obtained from each other only by switching the player who is supposed to win. Such type of reductions, though not with good complexity bounds, were also considered by Bernet, Janin and Walukiewicz [2]. The reachability game to which one reduces the parity game, can now be described as follows.

- The set $Q$ of nodes of the reachability game consists of nodes of the form $(a, p, \tilde{b})$ where $a$ is a node of the parity game, the player $p \in \{\text{Anke}, \text{Boris}\}$ moves next and $\tilde{b}$ represents the winning statistics of Anke.
- The starting node is $(s, p, \tilde{0})$, where $\tilde{0}$ is the vector of all $b_i$ with value 0, $s$ is the starting node of the parity game and $p$ is the player who moves first.
- Anke can move from $(a, \text{Anke}, \tilde{b})$ to $(a', \text{Boris}, \tilde{b}')$ iff she can move from $a$ to $a'$ in the parity game and this move causes Anke's winning statistics to be updated from $\tilde{b}$ to $\tilde{b}'$ and $\tilde{b}$ does not yet indicate a win of Anke.
- Boris can move from $(a, \text{Boris}, \tilde{b})$ to $(a', \text{Anke}, \tilde{b}')$ iff he can move from $a$ to $a'$ in the parity game and this move causes Anke's winning statistics to be updated from $\tilde{b}$ to $\tilde{b}'$ and $\tilde{b}$ does not yet indicate a win of Anke.

The number of elements of $Q$ can be bounded by $O(n^4)$. First note that the number of increasing functions from $\{0, 1, \ldots, \lceil \log(n) \rceil + 2\}$ to $\{1, 2, \ldots, \lceil \log(n) \rceil\}$ can be bounded by $O(n^2)$, as any such sequence $(b'_0, b'_1, \ldots, b'_{\lceil \log(n) \rceil + 2})$ can be represented by the subset $\{b'_k + k : 0 \leq k \leq \lceil \log(n) \rceil + 2\}$ of $\{1, 2, \ldots, 2\lceil \log(n) \rceil + 2\}$ and that there are at most $O(n^2)$ such sets. Further, note that $b'_k \leq b'_{k+1}$ implies $b'_k + k < b'_{k+1} + k + 1$ and thus all $b'_k$ can be reconstructed from the set. Given a winning statistics $\tilde{b} = (b_0, b_1, \ldots, b_{\lceil \log(n) \rceil + 2})$, one defines $b'_0 = \max\{1, b_0\}$ and $b'_{k+1} = \max\{b'_k, b_{k+1}\}$ and notes that only those $b_k$ with $b_k = 0$ differ from $b'_k$. Thus one needs $\lceil \log(n) \rceil + 3$ additional bits to indicate which $b_k$ is 0. The overall winning statistics can then be represented by $3\lceil \log(n) \rceil + 5$ bits. Furthermore, one needs 1 bit to represent the player and $\lceil \log(n) \rceil$ bits to represent the current node in the play. Accordingly, each node in $Q$ can be represented with $4\lceil \log(n) \rceil + 6$ bits resulting in $O(n^4)$ nodes in $Q$. The set $Q$ itself can be represented by using a set of such representations of nodes.

The reachability game can be decided in time $O(|Q| \cdot n)$ by a well-known algorithm. For the general case of a reachability game, the time complexity is linear in the number of vertices plus number of edges of the game graph. The algorithm is listed explicitly by Khaliq and Imran [45] and appeared much earlier in the literature, though in other or only related settings [1, 16, 34, 37, 39]. □

This special case shows that, for each constant $m$, the parity game with $n$ nodes having values from $\{1, 2, \ldots, m\}$ can be solved in time $O(n^5) + g(m)$, for some function $g$ depending only on $m$, and the constant in $O(n^5)$ being independent of $m$. Such problems are called fixed parameter tractable (**FPT**), as for each fixed parameter $m$ the corresponding algorithm runs in polynomial time and this polynomial is the same for all $m$, except for the additive constant $g(m)$ depending only on $m$.

The main complexity classes for a problem of size $n$ (for example nodes in a game) and a parameter $m$ (for example the number of values in a parity game or the number of colours in a coloured Muller game) are **FPT** of problems which can be solved in time $f(m) \cdot n^k$ or time $g(m) + n^{k+1}$ for some constant $k$ and functions $f, g$ and **XP** of problems which can be solved in time $O(n^{f(m)})$ for some function $f$. Between **FPT** at the bottom and **XP** at the top are the levels of the **W**-hierarchy $\mathbf{W[1]}, \mathbf{W[2]}, \ldots$; it is known that **FPT** is a proper subclass of **XP** and it is widely believed that all these levels of the hierarchy are different. Note that the **NP**-complete problems are spread out over all the levels of this hierarchy and that even the bottom level **FPT** also contains sets outside **NP**. The level of a problem can depend on the choice of the parameter $m$ to describe the problem, therefore one has to justify the choice of the parameter $m$ which, in the present work, is a very natural parameter of the problem (number of values or colours of the game). The interested reader is referred to the books of Downey and Fellows [20, 21] and Flum and Grohe [25] for further information on parameterised complexity.

The next result carries over the methods of Theorem 2.8 to the general case, that is, use everything except those parts which make use of $\log(m) \leq n$. So the size of the code representing a winning statistics for Anke is given by $\lceil \log(n) \rceil + 3 \leq \log(n) + 4$ numbers of $\lceil \log(m + 1) \rceil \leq \log(m) + 1$ bits. As $\log(m) \leq \log(n)$, the overall size of represention of a node in the set $Q$ of nodes of the reachability game can be bounded by $\log(n) \cdot (\log(m) + 5) + c$. Hence, the size of $|Q|$ is $O(n^{\log(m)+5})$ and the number of edges in the reachability game is $O(n^{\log(m)+6})$.

One can combine this with the usual repeated tests for various types of **NP**-problems, which needs an additional factor of $n \cdot \log(n)$ for finding the winning strategy.

**Theorem 2.9.** *There is an algorithm which finds the winner of a parity game in time $O(n^{\log(m)+6})$ for a parity game with $n$ nodes and values from $\{1, 2, \ldots, m\}$. Furthermore, the algorithm can compute a memoryless winning strategy for the winner in time $O(n^{\log(m)+7} \cdot \log(n))$.*

Follow-up work obtained better bounds on the run-time by using that the translation into the reachability game provides a game with at most

$$\binom{m + 2 \cdot (\lceil \log(n) \rceil + 3)}{\lceil \log(n) \rceil + 3} \cdot n^2$$

edges. This led to the bound $O(2^m \cdot n^4)$ [12] which is based on the fact that $\binom{i}{j} \leq 2^i$ for all $i, j$. A further estimate can be obtained by slightly increasing the binomial upper bound to

$$\binom{(\lceil m/\log(n) \rceil + 2) \cdot (\lceil \log(n) \rceil + 3)}{\lceil \log(n) \rceil + 3} \cdot n^2$$

and then using common estimates on binomials, where the upper number is a multiple of the lower number. The calculations provide a runtime bound of

$$O(\lceil m/\log(n) \rceil^4 \cdot n^{3.45+\log(\lceil m/\log(n) \rceil + 2)});$$

this and similar bounds of this type were obtained by several researchers [22, 33, 43, 60] and subsequent improvements included replacing the term $n^2$ in the above formulas by the number of edges in the parity game [22, 33, 43].

The main improvement over the current algorithm by followup work is, however, the usage of space. The current algorithm uses quasipolynomial time and quasipolynomial space. Subsequent work has brought down this complexity from quasipolynomial to quasilinear [22, 43].

## 3 PARITY GAMES VERSUS MULLER GAMES

Muller games are a well-studied topic [6, 7, 48, 62, 64] and they had been investigated as a general case already before researchers aimed for the more specific parity games. A Muller game $(V, E, s, G)$ consists of a directed graph $(V, E)$, a starting node $s$ and a set $G \subseteq \{0, 1\}^V$. For every infinite play starting in $s$, one determines the set $U$ of nodes visited infinitely often during the play: if $U \in G$ then Anke wins the play else Boris wins the play. In a Muller game the complement of $G$ is closed under union iff for all $U, U' \notin G$, the set $(U \cup U')$ is not in $G$.

For complexity assumptions, it is natural to consider the case where $G$ is not given as an explicit list, but as a polynomially sized polynomial time algorithm computing the membership of a set $U$ (given by its explicit list) in the set $G$ or some similar equivalent effective representation. The reason for considering such a representation for $G$ is that Horn [36] showed that if $G$ is given as an explicit list of all possible sets of nodes infinitely visited when Anke wins, then the resulting game is solvable in polynomial time in the sum of the number of nodes and the number of explicitly listed sets. Hence, only more flexible ways of formulating winning conditions permit to cover interesting cases of Muller games.

For Muller games, Björklund, Sandberg and Vorobyov [4] considered a parameter which is given by the number of colours. For this, they assign to every node a value or colour from $\{1, 2, \ldots, m\}$ and take $G$ to be some set of subsets of $\{1, 2, \ldots, m\}$. Then $U$ is not the set of infinitely often visited nodes, but instead, the set of colours of the infinitely often visited nodes. Again, if $U \in G$, then Anke wins the play, else Boris wins the play. Coloured Muller games permit more compact representations of the winning conditions. In the worst case there is a $2^m$-bit vector, where $m$ is the number of colours; however, one also considers the case where this compressed winning condition is given in a more compact form, say by a polynomial sized algorithm or formula.

In the following, the interactions between Muller games, memoryless winning strategies and parity games are presented. The first result is due to Zielonka [64, Corollary 11] and the second one is in the thesis of Hunter [38].

**Theorem 3.1 (Zielonka [64]).** *Given a Muller game $(V, E, s, G)$, assume that the complement of the set $G$ of winning conditions is closed under union. Now, if Anke has a winning strategy in this Muller game then Anke has also a memoryless winning strategy.*

As a parity game is also a Muller game in which $G$ is closed under union for both Anke and Boris, the following corollary holds.

**Corollary 3.2 (Emerson and Jutla [28], Mostowski [49]).** *The winners in parity games have memoryless winning strategies.*

Hunter [38, page 23] found a characterisation for Muller games. Note that McNaughton [48] also investigated Muller games with memoryless strategies and characterised them through the concept of splitting [48], which is just another way of stating that both $G$ and its complement are union-closed. However, his paper does not connect these Muller games with parity games explicitly.

**Theorem 3.3 (Hunter [38]).** *Every Muller game $(V, E, s, G)$ in which both $G$ and its complement are closed under the union operation is a parity game and the translation can be done in polynomial time whenever the winning set $G$ can be decided in polynomial time.*

Besides the standard coloured Muller game of Björklund, Sandberg and Vorobyov [4], one can also consider the memoryless coloured Muller game. These are considered in order to see whether the game is easier to solve if one permits Anke only to win when she follows a memoryless strategy, otherwise she looses by the rules of the game. The main finding is that while memoryless coloured Muller games are, on one hand, easier in terms of the complexity class to which they belong, and, on the other hand, their time complexity is worse and one cannot exploit small numbers of colours as well as in Muller games. This is the main message of the following lines.

Björklund, Sandberg and Vorobyov [4] proved that the coloured Muller game is fixed-parameter tractable iff the parity game is fixed-parameter tractable (with respect to the number of values $m$ of the parity game). It follows from Theorem 2.8 that also the coloured Muller game is fixed-parameter tractable.

More precisely, McNaughton [48] and Björklund, Sandberg and Vorobyov [4] showed that a coloured Muller game with $m$ colours and $n$ nodes can be translated into a parity game with $2m$ colours and $m! \cdot n$ nodes. Note that $\log(m! \cdot n) \geq 2m$ for all $m \geq 24$ and $n \geq m$: $\log(m!) \geq \log(8^{m-8}) \geq 3 \cdot (m-8) = 3m - 24$. For $m \geq 24$, $3m - 24 \geq 2m$. Thus, the remaining cases can be reduced to finite ones by observing that for all $m$ and $n \geq \max\{m, 2^{48}\}$, $\log(m! \cdot n) \geq 2m$. So, for almost all pairs of $(m, n)$, $\log(m! \cdot n) \geq 2m$ and therefore one can use the polynomial time algorithm of Theorem 2.8 to get the following explicit bounds.

**Theorem 3.4.** *One can decide in time $O(m^{5m} \cdot n^5)$ which player has a winning strategy in a coloured Muller game with $m$ colours and $n$ nodes.*

For the special case of $m = \log(n)$, the corresponding number of nodes in the translated parity game is approximately $n^{\log(\log(n))+2}$ and the polynomial time algorithm of Theorem 2.8 becomes an $O(n^{5\log\log(n)+10})$ algorithm. The algorithm is good for this special case, but the problem is in general hard and the algorithm is slow.

Rabin games and Streett games are games where the winning set $G$ of the game is determined by a list of pairs of sets of nodes $(A_1, B_1), (A_2, B_2), \ldots, (A_m, B_m)$. Now, in the Rabin case, Anke wins a play iff there is an $i$ such that the set of infinitely often visited nodes $U$ intersects $A_i$ and is disjoint to $B_i$, in the Streett case, Anke wins a play iff all $i$ satisfy that either $U$ intersects $A_i$ or is disjoint to $B_i$. Rabin games and Streett games can be translated

into Muller games by doubling up the number of colours, that is an $n$-node Rabin game or Streett game with $m$ conditions can be translated into an $n$-node Muller game and $2m$ colours. The game graph remains exactly the same and each node caries between 0 and $2m$ colours, more precisely for each of the pairs $(A_i, B_i)$ of the Rabin condition, a node $v$ carries the colour $a_i$ if $v \in A_i$ and the colour $b_i$ if $v \in B_i$. Player Anke wins a play in the Rabin game iff the set $U$ of infinitely often visited nodes satisfies that, for some $i$, some node in $U$ has colour $a_i$ while no node in $U$ has colour $b_i$. The winning condition for the Streett game is complementary.

Now one can decide in time $O((2m)^{10m} \cdot n^5)$ which player is the winner of the Rabin game or Streett game. Alternatively, one can use the direct translation of Rabin games and Streett games to parity games [4, 48], which they used to show that these games are in **FPT** iff parity games are. This translation increases the number of nodes by a factor $m! \cdot m^2$ and the colours by a factor 2 and gives better bounds for the final algorithm of approximately $O(m^{5m} \cdot n^5)$, which is the same bound as the Muller game has. A direct solution without translating into other games by Piterman and Pnueli [53] has the runtime $O(n^{m+1} \cdot m!)$.

One might ask whether this bound can be improved. Björklund, Sandberg and Vorobyov [4] showed that under the Exponential Time Hypothesis it is impossible to improve the above algorithm to $O(2^{o(m)} \cdot n^c)$, for any constant $c$. Here the Exponential Time Hypothesis says that the problem **3SAT** with $n$ variables is not solvable in time $O(2^{o(n)})$. The following result enables to get a slightly better lower bound based on the more likely assumption that **FPT** $\neq$ **W[1]**. Here a dominating set of a graph is a set of nodes such that from every node in the graph there is an edge to one of the nodes in the dominating set; for this property one deviates from the usual convention of the non-existence of self-loops and assumes that every node has a loop to itself.

**Theorem 3.5.** *Given a graph $H$ with $n$ nodes and a number $m$ with $1 \leq m \leq n$, one can compute in time polynomial in $n'$ a coloured Muller game with $n'$ nodes and $m'$ colours such that, for all sufficiently large $m, n$,*

- *$m' \leq (4m/\log(m)) \cdot \log(n)$,*
- *$n' \leq n^{(4m/\log(m))+4}$ and*
- *the given graph $H$ has a dominating set of size up to $m$ iff player Anke has a winning strategy in the resulting coloured Muller game.*

*Furthermore, the winning set of Boris is closed under union and therefore, whenever Anke has a winning strategy, she has a memoryless winning strategy.*

**Proof.** Assume that the given graph $H$ has vertices $\{a_1, \ldots, a_n\}$ and let $E$ be the set of its edges. Without loss of generality assume that $n, m \geq 2$ so that $\log(n), \log(m)$ are at least 1.

The main complexity bound in the parity game is due to some compression of $m$-tuples. Instead of giving a plain $m$-tuple of $m \cdot \lceil \log(n) \rceil$ bits, one stores the $m$-tuple in subsets of a base set $E$ of colours.

Let $\{a_{k_1}, a_{k_2}, \ldots, a_{k_m}\}$ be Anke's choice of the dominating set in the graph $H$. The idea is to code each sequence $a_{k_1}, a_{k_2}, \ldots, a_{k_h}$ of nodes as a subset of $h \cdot \lceil \log(n)/\log(m) \rceil$ colours from a set $E$ of $(2m + 2) \cdot \lceil \log(n)/\log(m) \rceil$ colours. Note that for each subset $E'$

of $E$ with at most $m$ colours, there is a one-one mapping $f_{E'}$ from $\{a_1, \ldots, a_n\}$ to subsets of $E$ such that $f_{E'}(a_\ell)$ is the disjoint union of $E'$ and a set of $\lceil \log(n)/\log(m) \rceil$ colours. This one-one function exists, as $|E - E'|$ has at least $\lceil \log(n)/\log(m) \rceil \cdot (m + 2)$ elements and

$$|E - E'|! / (\lceil \log(n)/\log(m) \rceil! \cdot (|E - E'| - \lceil \log(n)/\log(m) \rceil)!)$$

$$\geq m^{\lceil \log(n)/\log(m) \rceil} \geq 2^{\log(m) \cdot \log(n)/\log(m)} = 2^{\log(n)} = n.$$

Next one inductively defines

- $f(a_{\ell_1})$ as $f_\emptyset(a_{\ell_1})$;
- for $h = 0, 1, \ldots, m - 1$, $f(a_{\ell_1}, \ldots, a_{\ell_h}, a_{\ell_{h+1}}) = f_{E'}(a_{\ell_{h+1}})$ where $E' = f(a_{\ell_1}, \ldots, a_{\ell_h})$ and $\ell_1, \ell_2, \ldots \in \{1, 2, \ldots, n\}$.

Now the idea of the game constructed for the reduction is that Boris repeatedly asks Anke to 'find an edge in $H$ from a given $a_i$ into some $a_j$ of the dominating set', for various values of $a_i$; this is represented in the game by Anke going through her dominating set $a_{k_1}, a_{k_2}, \ldots, a_{k_m}$ by inductively visiting nodes of the game corresponding to $a_{k_1}, a_{k_2}, \ldots, a_{k_h}$ for $h = 0, 1, \ldots$ until an $h$ is reached with $a_{k_h} = a_j$. In case these answers are inconsistent for some choices $a_i$ and $a_{i'}$ that is, there is an $h$ such that for both choices $a_i$ and $a_{i'}$, Anke goes through nodes of the game corresponding to $a_{k_1}, a_{k_2}, \ldots, a_{k_{h-1}}$ but then goes through nodes corresponding to $a_\ell$ and $a_{\ell'}$, with $a_\ell \neq a_{\ell'}$, for $a_i$ and $a_{i'}$ respectively, then Boris will ask Anke to do this repeatedly for an infinite number of times and win the game.

Now the constructed Muller game is defined more formally. For this, in addition to the colours $E$, the colours $\{d_0, d_1, \ldots, d_m\}$ are also used, where $E \cap \{d_0, d_1, \ldots, d_m\} = \emptyset$. Note that there are in total $(2m + 2) \cdot \lceil \log(n)/\log(m) \rceil$ colours in $E$ and $m + 1$ colours in $D = \{d_0, d_1, \ldots, d_m\}$.

To simplify the presentation, in the description below a node $w$ can have several colours from $D \cup E$, instead of only one colour. This convention does not affect the generality, as the node $w$ can be replaced by a sequence of up to $|D \cup E| + 1$ nodes, where each node in the sequence has one colour from the set of colours assigned to $w$ and only one choice for next move; one colour might need to be repeated in order to fix the player that moves next. All nodes will have at least the colour $d_0$, so that there are no colourless nodes.

Boris wins a play iff the colours of infinitely often visited nodes consist, for some $h$, exactly of the set $\{d_0, d_1, \ldots, d_h\}$ and at least $h \cdot \lceil \log(n)/\log(m) \rceil + 1$ of the colours in $E$. Note that Boris' winning condition from above is closed under union. Given two winning conditions $U, U'$ for Boris, there are $h, h'$ such that

- $U$ has at least $h \cdot \lceil \log(n)/\log(m) \rceil + 1$ colours from $E$ and the colours $\{d_0, d_1, \ldots, d_h\}$ and
- $U'$ consists of at least least $h' \cdot \lceil \log(n)/\log(m) \rceil + 1$ colours from $E$ and the colours $\{d_0, d_1, \ldots, d_{h'}\}$ and
- $U \cup U'$ has at least $\max\{h, h'\} \cdot \lceil \log(n)/\log(m) \rceil + 1$ colours from $E$ and the colours $\{d_0, d_1, \ldots, d_{\max\{h, h'\}}\}$.

Thus $U \cup U'$ is also a valid winning condition of Boris. For this reason, it is sufficient to consider memoryless winning strategies of Anke. The nodes of the game and their colours are as follows:

1. Starting node $(start)$ with colour $\{d_0\}$, from where Boris moves to any node of the form $(edge, a_i)$ described in item 2.

2. For $i \in \{1, 2, \ldots, n\}$, node $(edge, a_i)$ with colour $\{d_0\}$. From node $(edge, a_i)$ Anke can move to nodes $(a_j, a_{k_1}, f(a_{k_1}))$ described in item 3 such that $(a_i, a_j)$ is an edge in the graph $H$.

3. For $j, k_1, k_2, \ldots, k_h \in \{1, 2, \ldots, n\}$, node $(a_j, a_{k_h}, f(a_{k_1}, a_{k_2}, \ldots, a_{k_h}))$ with colours $f(a_{k_1}, a_{k_2}, \ldots, a_{k_h}) \cup \{d_0, d_1, d_2, \ldots, d_h\}$. Boris can move from node $(a_j, a_{k_h}, f(a_{k_1}, \ldots, a_{k_h}))$ to a node as described below:
   (a) always to nodes $(edge, a_i)$ for $i$ with $1 \leq i \leq n$;
   (b) if $h < m$ and $a_j \neq a_{k_h}$, then also to the node $(nextround, a_j, f(a_{k_1}, \ldots, a_{k_h}))$, described in item 4;
   (c) if $h = m \wedge a_j \neq a_{k_h}$, then also to the node $(fail)$ described in item 5.

4. For $h$ with $1 \leq h < m$ and $j, k_1, k_2, \ldots, k_h \in \{1, 2, \ldots, n\}$, node $(nextround, a_j, f(a_{k_1}, a_{k_2}, \ldots, a_{k_h}))$ with colours $f(a_{k_1}, a_{k_2}, \ldots, a_{k_h}) \cup \{d_0, d_1, \ldots, d_h\}$. Anke can move from a node $(nextround, a_j, f(a_{k_1}, \ldots, a_{k_h}))$ to a node of the form $(a_j, a_{k_{h+1}}, f(a_{k_1}, \ldots, a_{k_h}, a_{k_{h+1}}))$, for $a_{k_{h+1}}$ being a node in $H$, as described in item 3. Here Anke should choose $a_{k_{h+1}}$ according to her dominating set in the graph $H$, as otherwise she would lose based on the winning conditions of Boris.

5. Node $(fail)$, with colours $D \cup E$, the players can only move from $(fail)$ to $(fail)$.

So in total there are $|E| + m + 1$ colours and their number can be bounded by $m' = 4m \cdot \log(n)/\log(m)$ for all sufficiently large $m$. Furthermore, there are

- 1 node according to item 1,
- $n$ nodes according to item 2,
- at most $2^{m'} \cdot n^2$ nodes according to item 3,
- $2^{m'} \cdot n$ nodes according to item 4 and
- 1 node according to item 5.

These $2^{m'} \cdot (n^2 + n) + n + 2$ nodes can be translated into at most $2^{m'} \cdot (n + 1)^2 \cdot (m' + 1)$ nodes in the regular Muller games, with one colour each, as indicated above. Using $m' \leq 4m \cdot \log(n)/\log(m)$ and $m \leq n$, this number of nodes can be bounded by $n^{4m/\log(m)} \cdot (n + 1)^2 \cdot (4n \log(n) + 1)$ which is bounded by $n' = n^{(4m/\log(m))+4}$ for all sufficiently large $n$. Thus, $m'$ and $n'$ are almost always upper bounds on the number of colours and nodes, respectively.

For the verification, it is shown that Anke wins the game iff there is a dominating set of size at most $m$ in the original graph. If there is a dominating set $\{a_{k_1}, a_{k_2}, \ldots, a_{k_m}\}$, for each choice $(edge, a_i)$ made by Boris (whenever it is Boris's turn) Anke always chooses $a_j \in \{a_{k_1}, a_{k_2}, \ldots, a_{k_m}\}$ such that $(a_i, a_j)$ is an edge in $H$ and moves to $(a_j, a_{k_1}, f(a_{k_1}))$. Then, Anke goes through choices $(a_j, a_{k_h}, f(a_{k_1}, a_{k_2}, \ldots, a_{k_h}))$, for $h = 2, 3, \ldots$, until Boris chooses $(edge, a_{i'})$ in its turn. Note that this will happen when $a_{k_h} = a_j$ or earlier. The maximal $h$ such that $a_j = a_{k_h}$ is chosen in the play, will make the set of infinitely often visited colours $U = f(a_{k_1}, \ldots, a_{k_h}) \cup \{d_0, d_1, \ldots, d_h\}$, which has only $h \cdot \lceil \log(n)/\log(m) \rceil$ colours from $E$ and therefore it will be a win for Anke and not for Boris.

In the case that there is no dominating set, the play will either end up in the node $(fail)$ or Anke would not be using its dominating set consistently as illustrated below. One assumes that Anke plays a memoryless winning strategy and that Boris knows Anke's strategy; thus it is sufficient to show that Boris can counteract this strategy. So assume that there is no dominating set of size $m$. There are two cases.

(a) Anke does not consistently maintain the same candidate for a dominating set. Then there are two nodes $a_i, a_{i'}$ such that, when Boris asks Anke to follow an edge from $a_i$ and $a_{i'}$, respectively, into the dominating set then Anke's answers are not consistent. More precisely, there are $a_i$ and $a_{i'}$, such that, in the case that the play goes to nodes $(edge, a_i)$ and $(edge, a_{i'})$, Anke (in series of moves via nodes of item 2 and 3) chooses $(*, a_{k_1}, f(a_{k_1})), (*, a_{k_2}, f(a_{k_1}, a_{k_2})),$ $\ldots, (*, a_{k_{h-1}}, f(a_{k_1}, a_{k_2}, \ldots, a_{k_{h-1}}))$, and then chooses

$$(*, a_{k_h}, f(a_{k_1}, a_{k_2}, \ldots, a_{k_{h-1}}, a_{k_h})) \text{ or}$$
$$(*, a'_{k_h}, f(a_{k_1}, a_{k_2}, \ldots, a_{k_{h-1}}, a'_{k_h})),$$

respectively, where $a_{k_h} \neq a'_{k_h}$ and $*$ can be any $a_j \in \{a_1, a_2, \ldots, a_n\}$. Boris exploits this inconsistency by moving to $(edge, a_i)$ at the start of the play and by alternately choosing $(edge, a_{i'})$ and $(edge, a_i)$ when the play enters

$$(*, a_{k_h}, f(a_{k_1}, a_{k_2}, \ldots, a_{k_h})) \text{ or } (*, a'_{k_h}, f(a_{k_1}, a_{k_2}, \ldots, a'_{k_h})).$$

As Anke plays a memoryless strategy, the play will result in an infinite loop of nodes with the colours $f(a_{k_1}, a_{k_2}, ..., a_{k_{h-1}}, a_{k_h}) \cup$ $f(a_{k_1}, a_{k_2}, ..., a_{k_{h-1}}, a'_{k_h}) \cup \{d_0, d_1, ..., d_{h-1}, d_h\}$ and the resulting play is won by Boris.

(b) Anke maintains consistently the same candidate for a dominating set $\{a_{k_1}, a_{k_2}, \ldots, a_{k_m}\}$. As this candidate is not a dominating set, there is some $a_i$ such that no edge goes from $a_i$ into this candidate set. So Boris chooses $(edge, a_i)$ and Anke moves to a node $(a_j, a_{k_1}, f(\{a_{k_1}\}))$. Now the play will go through all rounds and at each round through the node $(a_j, a_{k_h}, f(a_{k_1}, \ldots, a_{k_h}))$ and as $a_j \neq a_{k_h}$, Boris can continue the play up until it reaches $(fail)$. Then the play will remain in that node forever and as $E \cup D$ is a set of colours which is in the winning condition of Boris, Boris will win this play as well. □

Note that the above algorithm reduces the question whether a graph of $n$ nodes has a dominating set of size $m$ to a Muller game with up to $m' = (4m/\log(m))\log(n)$ colours and $n' = n^{(4m/\log(m))+4}$ nodes, for sufficiently large $m$ and $n$. The construction of the game takes time $O(n')$. Assuming now that there is a decision procedure for Muller games which takes time $(2^{m'} \cdot n')^c$, for some constant $c$, one can obtain a decision procedure for the previous dominating set problem in time $n^{c \cdot ((8m/\log(m))+4)}$, where the exponent is clearly $o(m)$. Chen, Huang, Kanj and Xia [15, Theorem 5.4] showed that if there is an algorithm which solves dominating set problem with these parameters – note that their paper uses a different notation – then $\textbf{FPT} = \textbf{W}[1]$. This provides the following corollary.

**Corollary 3.6.** *For every $c$ there is no algorithm running in time* $O((2^m \cdot n)^c)$ *which decides the winner of a coloured Muller game with $n$ nodes and $m$ colours unless $\textbf{FPT} = \textbf{W}[1]$.*

The above reduction, due to the optimisation involved, increased massively the number of nodes in the game. If one does not want to lower the factor $m$ to $(m/\log(m)) \cdot \log(n)$ in the translation, but only cares to achieve $O(m \cdot \log(n))$ colours, then there are more straightforward methods. One might ask whether there is a translation which uses less nodes but increases the number of colours massively. Zielonka [64] used similar methods to show $\textbf{NP}$-hardness of the Muller games, even in the special case of games

where player Anke, in the case that she wins, also has a memoryless winning strategy.

**Theorem 3.7 (Zielonka [64]).** *The problem to determine whether Anke can win a Muller game when the set of Boris' winning conditions is closed under union is $\textbf{NP}$-complete; however, for containment in $\textbf{NP}$, the winning conditions have to be represented as in Zielonka's paper. In general, this problem is in $\Sigma_2^{\textbf{P}}$.*

Note that for games where Anke might win, but not with a memoryless winning-strategy, the complexity bound is worse. Dawar, Horn and Hunter showed that the problem to decide the winner in a Muller game is $\textbf{PSPACE}$-complete [17].

Memoryless games are games where Anke wins iff she (a) plays a memoryless strategy and (b) wins the game according to the specification of the game. If she does not do (a), this is counted as a loss for her. This was already done by Björklund, Sandberg and Vorobyov [4, Section 5] for Streett games and it can also be done for Muller games.

In contrast to normal coloured Muller games, the complexity of the memoryless games is different. Björklund, Sandberg and Vorobyov [4, Section 5] considered memoryless Streett games (called Quasi-Streett games in their paper) and showed that these are $\textbf{W}[1]$-hard. This result implies that memoryless coloured Muller games are $\textbf{W}[1]$-hard. Furthermore, on one hand, one can decide in $\Sigma_2^{\textbf{P}}$ whether Anke has a winning strategy: There is a memoryless strategy of Anke such that the graph obtained by fixing Anke's moves according to the strategy, does not allow Boris to reach a loop of length up to $2n^2$, where the set of colours of this loop is a non-member of $G$. On the other hand, the next result shows that unless $\textbf{NP}$ can be solved in quasipolynomial time there is no analogue of the translation of Björklund, Sandberg and Vorobyov [4] from memoryless coloured Muller games into parity games. In contrast, solving memoryless coloured Muller games with four colours is already $\textbf{NP}$-complete. So, unless $\textbf{P} = \textbf{NP}$, the problem is not even in $\textbf{XP}$.

**Theorem 3.8.** *Solving memoryless coloured Muller games with four colours is $\textbf{NP}$-hard.*

**Proof.** In the following, satisfiability is reduced to memoryless coloured Muller game as follows. For ease of writing the proof, Muller games where nodes determine the player moving are considered. This could be easily converted to a game where the moves of Anke and Boris alternate by inserting intermediate nodes if needed.

Suppose $x_1, x_2, \ldots, x_k$ are the variables and $y_1, y_2, \ldots, y_h$ are the clauses in a satisfiability instance. Without loss of generality assume that no variable appears both as positive and negative literal in the same clause. Then, the above instance of satisfiability is reduced to the following Muller game (where the graph is undirected graph):

1. $V = \{s\} \cup \{u_1, u_2, \ldots, u_k\} \cup \{v_1, v_2, \ldots, v_h\} \cup \{w_{i,j} : [1 \leq i \leq h]$ and $[1 \leq j \leq k]$ and $[x_j$ or $\neg x_j$ appears in the clause $y_i]\}$.

2. $E = \{(v_i, w_{i,j}), (w_{i,j}, x_j) : x_j$ or $\neg x_j$ appears in $y_i\} \cup \{(s, u_i) : 1 \leq i \leq k\}$.

3. The colours are $\{x, y, +, -\}$; $s$ has the colour $y$, all nodes $u_j$ have the colour $x$; all nodes $v_i$ have the colour $y$; for every node $w_{i,j}$ in the graph, if $x_j$ appears in the clause $y_i$ positively then the colour is $+$ else $\neg x_j$ appears in $y_i$ and the colour is $-$.

4. The winning sets for Boris are $\{x, +, -\}$ and all subsets of $\{y, +, -\}$; the winning sets for Anke are $\{x, +\}$, $\{x, -\}$, $\{x\}$ and all supersets of $\{x, y\}$.

Now it is shown that the instance of satisfiability problem is satisfiable iff Muller game is a win for Anke playing in a memoryless way.

Suppose the instance is satisfiable. Then fix a satisfying assignment $f(x_j)$ for the variables, and let $g(y_i) = j$ such that $x_j$ (or $\neg x_j$) makes the clause $y_i$ true. Now Anke has the following winning strategy: At node $v_i$, move to $w_{i,g(y_i)}$. At node $w_{i,j}$, if $g(y_i) = j$ then move to $u_j$ else move to $v_i$. Intuitively, at nodes $v_i$, Anke directs the play to the node $u_{g(y_i)}$ (via $w_{i,g(y_i)}$). Similarly, for the nodes $w_{i,j}$, Anke directs the play to $u_{g(y_i)}$ either directly or via nodes $v_i$ and $w_{i,g(y_i)}$.

Thus, clearly, if an infinite play goes through colour $y$ infinitely often, then it also goes through colour $x$ infinitely often; thus Anke wins. On the other hand, if an infinite play does not go through colour $y$ infinitely often, then the set of nodes the play goes through infinitely often is, for some fixed $j$, $u_j$ and some of the nodes of the form $w_{i,j}$. But then, by the definition of Anke's strategy, the play can only go through nodes of colour $-$ finitely often (if $f(x_j)$ is true) and through nodes of colour $+$ finitely often (if $f(x_j)$ is false). Thus, Anke wins the play.

Now suppose Anke has a winning strategy. If there is an $i$ such that Anke moves from $w_{i,j}$ to $u_j$ then let $f(x_j)$ be true if $x_j$ appears positively in clause $y_i$; else let $f(x_j)$ be false. If there is no $i$ such that Anke moves from $w_{i,j}$ to $u_j$ then truth value of $f(x_j)$ does not matter (and can assigned either true of false).

To see that above is a satisfying assignment, first note that for each clause $y_i$, there exists a $w_{i,j}$ such that Anke moves from $w_{i,j}$ to $u_j$. Otherwise, Boris can first move from start node to $u_j$ and then to $w_{i,j}$ such that $x_j$ appears in clause $y_i$; afterwards the play will go infinitely often only through a subset of the nodes of the form $v_i, w_{i,j}$ and thus the colours which appear infinitely often in the above play is a subset of $\{y, +, -\}$.

Furthermore, for no $j$ and two nodes $w_{i,j}$ and $w_{i',j}$ such that $x_j$ appears in $y_i$ and $\neg x_j$ appears in $y_{i'}$, does Anke move from $w_{i,j}$ and $w_{i',j}$ to node $u_j$. Otherwise, Boris could win by first moving from $s$ to $u_j$ and then alternately going to nodes $w_{i,j}$ and $w_{i',j}$. It follows that $f$ gives a satisfying assignment for the instance of satisfiability. $\square$

## 4 CONCLUSION

The progress reported in this paper shows that solving parity games is not as difficult as it was widely believed. Indeed, parity games can be solved in quasipolynomial time – the previous bounds were roughly $n^{O(\sqrt{n})}$ – and they are fixed parameter tractable with respect to the number $m$ of values (aka colours or priorities) – the previously known algorithms were roughly $O(n^{m/3})$. These results are in agreement with earlier results stating that parity games can be solved in **UP** $\cap$ **co**-**UP** [41] and that there are subexponential algorithms to solve the problem [44]. In spite of the current progress, *the original question, as asked by Emerson and Jutla [28] in 1991 and others, whether parity games can be decided in polynomial time still remains an important open question.*

The above results on parity games are then used to give an algorithm of runtime $O((m^m \cdot n)^5)$ for coloured Muller games with $n$ nodes and $m$ colours; this upper bound is almost optimal, since an algorithm with runtime $O((2^m \cdot n)^c)$, for some constant $c$, only exists in the case that **FPT** = **W[1]**, an assumption which is considered to be unlikely.

One might ask whether the results obtained for parity games permit further transfers to Muller games, for example, in the special cases where (a) player Anke can employ a memoryless winning strategy due to the special type of the game or (b) one does not permit player Anke to use other strategies than memoryless ones. Note that case (b) differs from case (a), as in case (b) the condition on using memoryless strategies can be restrictive while case (a) applies to Muller games of those types where one knows that "if Anke has a winning strategy then she has a memoryless winning strategy". Case (a) was analysed by McNaughton [48] and Zielonka [64]; it applies to Muller games where the winning condition of player Boris is closed under union [64].

The above mentioned lower bound directly also applies to case (a). For case (b), the complexity class of the general problem is also in the polynomial hierarchy but not **PSPACE**-complete (unless **PSPACE** = $\Sigma_2^P$) as the decision problem for coloured Muller games; however, the algorithmic bounds are much worse, as one can code **NP**-hard problems into instances with four colours.
